20. ABSTRACT (Continue on reverse side if necessary and identify by block number) <u>Virus Identification.</u> Soldado Rock virus was identified from ticks of the Seychelles; Pongola, a new Yague group virus from bats and human febrile cases, and an apparently new bunyavirus were identified from Uganda; a strain of West Nile virus from an apparently rabid dog in South Africa was identified; from Australia, a new tick-borne flavivirus was characterized (isolated from ticks of birds; Ross River virus was confirmed from serum of a case of epidemic polyarthritis and rash in Fiji; four strains of Sindbis were identified from		

Lake Nasser, Egypt; and six strains of dengue, type 4 as well as other as yet unidentified viruses from New Caledonia were studied. An isolate of Colorado tick fever was identified from human serum of the Netherlands in a traveller.

Virus taxonomy. The Sakhalin serogroup was shown to belong in the Nairovirus genus. The IFA test reactions and cross-reactions of Rift Valley fever and other Phlebotomus fever group viruses indicated that the IFA test is relatively specific.

Serologic surveys. Surveys of Ghana, Liberia, Cameroon and the Sudan showed widespread activity of arboviruses and indication of activity of Lassa virus and Ebola virus in several areas of Africa.

Development of techniques. The ELISA and ELFA techniques were adapted to measure antibody to yellow fever, California group viruses and Rift Valley fever. Antigen could be detected in mosquitoes infected with Guaroa and La Crosse viruses indicating this technique may be applicable to detect arboviruses in field-caught mosquitoes.

Biochemistry. Most orbiviruses were found to have 10-segmented genomes; surprisingly, Colorado tick fever was discovered to have 12 RNA segments. It may, therefore, belong to another taxonomic set different from the other orbiviruses as they are now known.

Distribution of reagents. As in previous years, the reference center distributed large numbers of cell lines, viruses, antigens, and sera on a world-wide basis.

Tests of reassortant Phlebotomus fever group viruses for enhanced virulence. Enhanced virulence was not found for cloned prototype Phlebotomus fever group viruses or their reassortants.

SUMMARY

Virus Identification. Two viruses isolated from Ornithodoros capensis and one virus from Rhipicephalus sanguineus ticks collected in the Seychelles Islands have been tentatively identified as Soldado Rock virus. Another virus has been isolated from Hyalomma a. anatolicum ticks collected in Bahrain and is currently being identified.

Four different viruses from Uganda were studied. An isolate from mosquitoes was identified as Pongola; an isolate from a fruit bat and from 4 human febrile cases was related to Yogue virus and is a new member of that group; an isolate from Amblyomma variegatum ticks was bunyavirus-like by electron microscopy but did not react serologically with other African viruses tested; and another isolate from human serum was chikungunya virus.

An interesting virus from brain of a South African dog suspected of rabies was West Nile virus, and another South African isolate from mosquitoes was Uganda S.

An agent from Ixodes uriae ticks of Macquarie Island, Australia was a new member of the group B tick-borne encephalitis complex, the first such member from south of the equator. Umbre virus of the Turlock group was identified for the first time from mosquitoes of Australia. Another virus from the serum of a patient in Fiji was closely related to Ross River virus, the cause of epidemic polyarthritis and rash.

Two new viruses from Culex mosquitoes from Brazil belonged to the Corriparta group. This is the first recognition of this group in the Americas.

A virus from soft ticks collected near Cape Frehel, France was a sub-type of Soldado Rock virus.

Four viruses from mosquitoes collected near Lake Nasser, Egypt were identified as Sindbis virus.

Six viruses from mosquitoes of New Caledonia were group B agents, at least one of these is dengue, type 4; nine additional isolates from mosquitoes and birds have been established but not yet grouped.

An isolate from human serum from a febrile patient bled in the Netherlands was Colorado tick fever virus. The patient had vacationed in the western U.S.A. and returned sick to Holland where he removed a tick from himself. This is an example of long-distance transport of a human viral pathogen.

An agent recovered from Dermacentor variabilis ticks in Canada was negative in testing with sera to 87 viruses; another agent from Ornithodoros maritimus ticks collected in herring gull nests in Morocco was identified as a virus closely-related to Chenuda of the Kemerovo group.

Virus taxonomy. Members of the Sakhalin serogroup were shown to be related by HI and fluorescent focus neutralization tests, and to belong to

the Nairovirus Supergroup. Multiple viruses in the supergroup and corresponding reference sera were supplied to the University of Alabama where studies of RNA and proteins showed that these viruses formed a new genus in the family Bunyaviridae.

Serologic surveys. Surveys were conducted with sera from Ghana, Cameroon, Sudan, and Liberia using the IFA test. Sera positive for Ebola and Marburg antibody were found in Ghana. The Ebola positive sera were collected one year before the first recorded Ebola outbreak. Five of 41 sera from Cameroon were positive also for Ebola and 16/196 human sera from Liberia had Lassa virus antibody.

Sera from Sudan contained IFA antibodies to West Nile, group A (probably Sindbis and chikungunya), Rift Valley fever, group Bunyamwera (probably Bunyamwera, Germiston, and Ilesha), Tataguine, Quarantil, Bwamba, Tahyna, Bangui or Zinga, and Sicilian sandfly fever viruses. Antibody to Ebola virus was also found.

Development of techniques and models. In further development of the use of RNA purification and gel electrophoresis, it was found that Colorado tick fever (CTF) virus contained 12 segments, 2 more than found in any other orbivirus. This surprising result may mean that CTF virus, believed to be an orbivirus, is in a different genus of the Reoviridae family.

The IFA test has proved rapid, sensitive, and for some families of viruses, widely cross-reactive. This test offers the possibility of rapid, inexpensive virus identification and survey for antibody. The technique was developed and tested for members of a number of serological groups of arthropod-borne viruses. Within arbovirus groups A, Bunyamwera, and PHL, the test was broadly cross-reactive and as such was useful as the first test of broad serological surveys.

The ELISA was developed for detection of antigen in mosquitoes and the ELISA and ELFA for detection of RVF antibody.

Distribution of reagents. The reference center distributed 668 ampoules of reference sera, viruses, and antigens during 1980; mosquito tick and vertebrate cell lines were also distributed. Of the viruses and immune reagents distributed, there were represented 196 different arboviruses.

FOREWARD

In conducting the research described in this report, the investigator adhered to the "Guide for Laboratory Animal Facilities and Care", as promulgated by the Committee on the Guide for Laboratory Animal Resources, National Academy of Sciences - National Research Council.

I. VIRUS TAXONOMY

Nairovirus Genus (J. Casals and G.H. Tignor). Evidence was given in the 1979 annual report that several antigenic groups of virus in the Bunyavirus-like and unclassified categories were distantly, but reproducibly related by several tests, particularly the HI test. These observations, showing the existence of a Nairovirus "supergroup," supplied the leading basis for the establishment of a new genus, Nairovirus, in the family Bunyaviridae. The antigenic groups thus linked were: CCHF, Nairobi sheep disease, Dera Ghazi Khan, Hughes and Qalyub.

Two tests with one sample of Sakhalin virus gave low titers by HI, 1:5 or 1:10, against CCHF and Dugbe antigens; this was considered insufficient evidence to justify incorporation of the Sakhalin group in the Nairovirus genus, unless it could be confirmed.

A new immune serum was prepared with Sakhalin virus and mice were also immunized with Avalon virus, another member of the Sakhalin group. These reagents were tested by HI against CCHF, Dugbe and Hazara antigens, with the result shown in Table 1. In view of these results it appears justifiable to include the Sakhalin group in the Nairovirus "supergroup"; biochemical investigation, to be carried out in another laboratory, will determine whether other properties warrant the inclusion of the Sakhalin group in the Nairovirus genus.

Serological relationships among members of the Phlebotomus fever group of viruses as determined by immunofluorescent assay (J. Meegan and D. Winograd) The immunofluorescent (IF) test has proved rapid, sensitive, inexpensive, and for some families of viruses, widely cross-reactive. We have explored the cross-reactivity of the IF test using viruses of the Phlebotomus fever groups (Phlebovirus), alphavirus, and bunyavirus to determine the applicability of IF as the initial screening test in serological surveys. Additionally, considering the growing importance of the IF test in the diagnosis of disease, it was important to understand the cross-reactions between human pathogenic viruses within serological groups.

Tables 2, 3, and 4 show the results to date. A comparison of the IF relationships in the Phlebotomus fever group with those determined by the hemagglutination-inhibition (HI), complement-fixation (CF) and neutralization (N) tests shows no consistent agreement. However, in all except a few cases there is either an HI, CF, or N cross-reaction wherever there is an IF cross. A notable exception is the reaction of antisera to Rift Valley fever (RVF) virus with sandfly fever Sicilian antigen. Since these viruses circulate in the same geographic area in northern Africa, this cross-reaction represents a diagnostic dilemma.

Table 1

Inclusion of the Sakhalin group of viruses in the Nairovirus genus

II. VIRUS IDENTIFICATION

ALPHAVIRUS

Fiji-41451. (B.Q.Chen, S.M. Buckley and J. Casals). The initial steps on the identification of this strain were reported in the 1979 Annual Report. The virus had been isolated by Dr. R. B. Tesh from the serum of a patient seen in the course of an epidemic of polyarthrititis in that island.

The agent could not be adapted to propagation in new born mice; hemagglutination antigens were prepared from Vero and BHK-21 cell cultures infected with the strain. An immune serum was prepared in mice by repeated inoculation of Vero-cell-propagated viruses. With these reagents, the Fiji strain was identified as Ross River virus or an agent very similar to Ross River virus, Tables 5 and 6.

EgAr 989, EgAr 996, EgAr 1003, and EgAr 1019 (R.E.Shope). Seven viruses isolated from Culex pipiens mosquitoes and one from Anopheles spp. collected in Aswan Governorate were supplied by Dr. Rifky El-Karamany and Dr. Imam Z. Imam of Cairo, Egypt. Four of the isolates were not viable. The other 4 were established in mice. In reciprocal cross-CF tests, these isolates reacted to titer with Sindbis antigen and antibody.

FLAVIVIRUS

CS-122 (A. Brescia and J. Casals). Identification of this strain, initiated in 1979, has now been completed. The strain was isolated by Dr. T. St. George, CSIRO, from Ixodes uriae nymphs collected on Macquarie island, in 1976. The strain was easily confirmed as being a group B virus by complement fixation (CF) and indirect immunofluorescence (IF) tests. Cross-CF tests showed that CS-122 was closer to the tick-borne group B viruses than to other flaviviruses, but easily distinguishable from them. The result of a CF test is shown in Table 7; in addition a CS-122 hyperimmune mouse serum gave negative reactions at dilution 1:8 with the following antigens: Banzi, dengue 2, dengue 4, Edge Hill, Kadam, KFD, Kokobera, Kunjin, MVE, Saboya, Sepik, SLE, Usutu and yellow fever.

CS-122 was compared with a strain of Central European Tick-borne encephalitis virus (ACA), in an intracerebral mouse neutralization test with the results shown in Table 8. In view of the CF and neutralization test results it is tentatively concluded that strain CS-122 is a new flavivirus, close to some of the members of the tick-borne virus complex than to the rest of flaviviruses.

SA AN - 2 (J. Kalunda and A. Mukuye). The strain was submitted by Dr. B. McIntosh, Durban, South Africa; it had been isolated from the brain of a dog which presented a rabies-like disease.

SA AN-24630 strain propagated easily in Vero and BHK-21 cell cultures with CPE appearing in 2 or 3 days; the strain killed newborn mice in 3 or 4 days. The strain was shown to belong in antigenic group B by testing

infected BHK-21 cultures against the following polyvalent grouping immune ascitic fluids by the IF test: groups A,B,C, Bunyavirus, Bwamba, California, Capim, Congo, Guama, Kemerovo, Palyam, phlebotomus fever, Quaranfil, rabies, Simbu, Tacaribe, VSV, and polyvalents #1, 2, 3, 4, 5, 6, 7, 8, 9, 10 and 12 (NIH, Catalogue of Research Reagents). A strong positive reaction was given by the group B ascitic fluid while all others were negative.

An immune mouse serum against SA AN 24630 prepared in South Africa, was tested by CF test against antigens derived from 47 different flaviviruses; the serum was tested in increasing two-fold dilutions beginning at 1:8 and the antigens were used in dilutions 1:4 and 1:16. The result of the test is given in Table 9. A second CF test confirmed the results shown in Table 9, and indicated the close relationship between SA AN 24630, West Nile and Kunjin. Since the latter has never been isolated in Africa, it was tentatively concluded that SA AN 24630 was a strain of West Nile; the result of a final CF test, Table 10, appears to confirm the conclusion.

SA Ar 19786 virus (I.Marika, G.Roze, and R.E.Shope). This virus was received from Dr. B. McIntosh of the South Africa Institute for Medical Research. It reacted by CF with the group B grouping fluid. A screening CF test detected cross-reactions with Usutu, Uganda S, yellow fever, and dengue 1 viruses; the following were negative: Banzi, Spondweni, Zika, Wesselsbron, Dengue 2 and 3, Ntaya and Kadam. A hemagglutinating antigen was prepared with optimum reactivity at pH 6.4-6.8. An HI test indicated a very close relationship of SA Ar 19786 virus to Uganda S (Table 11) and distinctness from Usutu, yellow fever, and dengue 1.

NC Ar 250 (R.E.Shope, P. Garbe, and G. Roze). Twenty virus strains were received from Dr. P. Fauran of the Institut Pasteur, Noumea, New Caledonia for identification. Five of these were not viable in mice. Of the others, NC Ar 250, NC Ar 254, NC Ar 262, NC Ar 264, NC Ar 281, and NC Ar 323 reacted with the group B grouping fluid by CF test. NC Ar 250 was studied further as a representative of these flaviviruses. Positive CF reactions were found with dengue viruses, types 1, 2 and 4. Nine other flaviviruses of Australia and Asia were negative. Reciprocal CF tests with dengue 1,2 and 4 showed strongest reactions with dengue, type 4 (Table 12). NC Ar 250 was thus presumptively identified as dengue virus, type 4.

Of the other New Caledonia isolates, NC Ar 238, NC Ar 259, NC Ar 265, NC Ar 267 and NC Ar 318 killed mice in less than 2 days. Identification of these is incomplete. NC Ar 280, NC Ar 309, NC Ar 318, and NC An 1 had incubation periods in mice greater than 2 days, did not react with the group B fluid, and remain unidentified.

Dak Ar D 14701 (T. Jamnback, G. Roze, and R.E.Shope). This virus was referred for identification by Dr. Y. Robin of the Institut Pasteur, Dakar. The virus is called Kedougou virus and was previously reported from YARU to be a probably new flavivirus. Three attempts to produce a hemagglutinating antigen from mouse brain by sucrose-acetone extraction were negative. Studies were done therefore by CF test. The antigen reacted with group B

grouping ascitic fluid, Ntaya (1:8), Usutu (1:32), West Nile (1:4), Zika (1:4), Spondweni (1:4), and dengue 1 (1:4). There was no reaction with Bouboui, yellow fever, Uganda S, Dengue 2, Dakar bat, Wesselsbron, or Banzi sera. Further, antigens of West Nile, Ntaya, dengue 1, and Usutu failed to react by CF with Dak Ar D 14701 ascitic fluid (homologous 128/256). The same homologous fluid did not inhibit Tembusu and Israel turkey meningoencephalitis HA antigens. Kedougou virus thus appears to be a new group B virus.

Japanese encephalitis virus (JE) virus from mosquitoes of Indonesia and relation of isolation frequency to vector density (J. Olson). The first isolation of JE from Indonesia was made from Culex tritaeniorhynchus collected in Kapuk, an area near Jakarta where pigs are raised (P.F.D. Van Peenen *et al.*, 1974, Milit. Med., 139: 821-823). Additional studies on the ecology of JE in this focus showed that swine were amplifying hosts of the virus and the Cx. tritaeniorhynchus served as the principal vector species (P.F.D. Van Peenen *et al.*, 1975, Trans. Roy Soc. Trop. Med. Hyg. 69: 477-479). The Virology and Entomology Departments of the U.S. Naval Medical Research Unit No. 2, Jakarta Detachment (NAMRU-2) began a study in October 1978 designed to test the hypothesis that JE activity was associated with vector density.

Mosquitoes were collected in 3 CDC light traps on each of 2 nights per month separated by 2-week intervals from October 1978 through May 1980. All blood fed female mosquitoes were held for 2 days to permit digestion of their blood meals, chilled, identified and separated by species into pools of approximately 50 each, and stored at -60°C. Each pool was thawed and triturated in phosphate buffered saline with bovine albumin added (pH 7.8 in a Ten Broeck grinder, centrifuged at 2113 xG for 20 minutes and the supernatant fluid stored at -60 °C until virus isolations were attempted.

Each triturated pool with antibiotics added was inoculated into tubes which contained a monolayer of green monkey kidney (Vero) and baby hamster kidney (BHK21) cells, respectively. Cells were observed daily for evidence of cytopathic effect (CPE) and negative blind passaged after 10 days. After 14 days subsequent to passage, specimens which failed to cause CPE were considered negative and discarded.

A total of 22 viruses were recovered from the 18,159 female Cx. tritaeniorhynchus mosquitoes in 366 pools. Six of these isolates have been identified as JE in a one-way microneutralization (Micro-Nt) test as described by T.G. Ksiazek and Liu (S.E. Asian J. Trop. Med. Publ. Hlth., (in press). Ten of the remaining 20 strains were lyophilized after passage in suckling mouse brain (smb) or cell culture to increase their titer and sent to YARU for identification. All but one strain was recovered and grown to sufficient titer for identification. Three of the 9 strains were tested by micro Nt in Vero cells using JE hyperimmune mouse ascitic fluid (HMAF) and tentatively identified as JE. Those strains which were not neutralized by anti-JE HMAF will be identified with other strains recovered from mosquitoes of Indonesia. Confirmation of the isolates presumptively identified as JE will be done by cross neutralization tests including other viruses and their antisera as well as HMAF prepared with

each field isolate. Table 13 gives the current status of the strains isolated from the study area.

BUNYAVIRUS

UG MP - 15332 (M. Kalunda and A. Mukuye). The strain was isolated from Aedes africanus wild-caught in Uganda, it produces CPE in Vero and BHK-21 cells and propagates well in newborn but not in adult mice. A sucrose-acetone antigen prepared from mouse brain tissue failed to agglutinate goose erythrocytes. Placement of the strain in an antigenic group was done by IF test; spot-slides carrying infected BHK-21 cells were tested against dilution 1:4 of the polyvalent grouping ascitic fluids listed above (see, SA AN 24630); in addition, the slides were tested with an Australian-viruses group antiserum (08174-6) and antisera against other Ugandan strains (Ug Sf 38485 and similar ones). A strong positive reaction was observed only with the Bwamba grouping reagent.

An antiserum for UG MP 15332 was next tested against antigens for the 6 viruses used in the preparation of the Bwamba polyvalent reagent, with the result shown in Table 14; the serum reacted only with Pongola and Bwamba antigens, with a higher titer with the former.

An additional CF test, Table 15, and a cross-neutralization test, Table 16, seemed to indicate that UG MP 15332 is a strain of Pongola virus.

Aus CH 19546 (R.E.Shope). This virus was referred for study by Dr. R. Doherty of the Queensland Institute for Medical Research, Australia. The original studies in this laboratory failed to detect relationship to other arboviruses. However, Dr. Doherty informed us that CH 19546 virus reacted by CF with the group Turlock grouping antibody. This relationship was confirmed. Neutralization test in baby mice with Aus CH 19546 virus and homologous and Umbre antibody indicated identity or a very close relationship (CH 19546 ascitic fluid LNI, greater than 5.0; Umbre serum LNI, greater than 5.0).

NAIROVIRUS

BREST AR/T 101 (K. Obom and J. Casals). This strain was isolated from Ornithodoros maritimus ticks collected in Brittany (France) in 1978, by Dr. C. Chastel, Medical School, Brest; the strain was found to be closely related to Soldado and confirmation was requested. Identification studies were begun in 1979 and completed this year.

The result of a CF test clearly shows, Table 17, that AR/T101 is closely related to Soldado virus (strain Cal AR 908). The results of neutralization test by intracerebral route in mice, Table 18, while confirming this conclusion as far as they go, were unsatisfactory owing to the low titers of the viruses.

More tests comparing AR/T 101 with additional strains of Soldado virus are required in order to decide whether this strain differs sufficiently and consistently from Soldado virus to justify considering it

as a new virus in the Hughes group; at the moment it seems adequate to consider BREST AR/T 101 a subtype of Soldado virus.

BREST AR/T 234. (J. Casals). Strain isolated from O. (A.) maritimus from Essaouira island, off Mogador, Morocco, in 1979; submitted by Dr. C. Chastel, who found the strain close to Soldado virus. The result of a CF test, Table 19, established that by this test the strain is indeed close to Soldado but distinct. It determines the relationship between this strain and the preceding one (Brest AR/T 101).

Omo. (J. Casals and R.E. Shope). Omo virus was isolated from the spleen of Mastomys spp. caught at Ethiopia, in the Omo River Valley, in 1971, and submitted by Dr. P. Ardoin, Pasteur Institute, Paris. Screening by CF test had shown (YARU Annual Report, 1973) that the virus was related to Qalyub virus. Continuation of these studies by CF have given the results shown in Table 20, which indicate that the two viruses, while closely related, appear to be distinguishable by this test. Comparison of the two agents by plaque reduction tests is planned.

ORBIVIRUS

MEUZ STRAIN (J. Casals). This agent was isolated from the blood of a febrile patient in Amsterdam, the Netherlands, by Dr. H.A.E. van Tongeren, of that city. The patient had traveled in the Rocky Mountains area during the late part of May, 1979, and developed a febrile illness with onset of June 2. This virus was isolated from blood taken on June 8; Dr. Tongeren suspected Colorado tick fever and submitted the virus for identification.

The result of a CF test, Table 21, with a hyperimmune mouse serum for the Meuz strain and a reference CTF immune serum showed that the new strain was similar to two CTF virus strains, 65-68 and Condon. Final identification was done by intracerebral mouse neutralization test with the result shown in Table 22. It appears that Meuz is a strain of CTF.

Fr Brest/Ar/T222 (A.J.Main). This strain originally isolated from a pool of 10 adult female Ornithodoros maritimus collected from herring gull nests on Essaouira Island, near Mogador, Morocco during June 1979, was submitted for identification by Dr. C. Chastel of Brest, France. Complement-fixation and plaque-reduction neutralization tests indicate that it is a member of the Chenuda complex of the Kemerovo serogroup close to Chenuda and Baku, Table 23.

BeAr 236191 and BeAr 295042 (D.L.Knudson). These two viruses from Culex mosquitoes were referred by Dr. F. Pinheiro, Belem, Brazil with information that they reacted with NIH polyvalent Palyam-Corriparta grouping fluid. CF tests at YARU confirmed the reactivity with the grouping fluid and demonstrated that the 2 Brazilian isolates belong in the Corriparta serogroup, Table 24.

RHABDOVIRUS

Natal bat virus (G.H.Tignor and J. Crick). A virus isolated from bats

in South Africa was sent by Dr. C. D. Meredith of the Institute for Virology, Sandringham. In June, 1980, an outbreak of bat rabies in Durban, Natal concurrent with an epizootic of dog rabies was noted. The Natal bat virus was initially tested by CF with rabies virus at YARU and shown to differ. Subsequent CF tests indicate that Natal bat virus is identical or closely-related to Lagos bat virus Table 25. This is the first isolate of Lagos bat virus in South Africa.

UNCLASSIFIED

Ug Z-52969. (M. Kalunda and A. Mukuye). The strain was isolated from the viscera of a fruit bat, Rousetus aegyptiacus, in Uganda; a second, similar strain was isolated from another bat of the same species at about the same time. Furthermore, shortly after the virus was introduced in the Entebbe laboratory, four additional strains of what appeared to be the same agent were isolated from laboratory workers who had developed a mild to severe illness.

Work in this laboratory showed that the virus propagated in Vero and BHK-21 cells in the absence of CPE; the agent killed newborn and adult mice. IF tests with polyvalent grouping immune ascitic fluids and with a hyperimmune Lassa virus antiserum gave negative results.

A hyperimmune mouse serum for UG Z-52969 in serial two-fold dilutions beginning at 1:4 was tested by CF test against 79 different antigens; and 22 antisera for viruses not included in the polyvalent grouping reagents, Table 26, were similarly tested against an antigen for this strain. The only cross-reaction noticed in these tests was with Yogue virus. Additional CF tests clearly established the relationship between Ug Z-52969 and Yogue, Table 27, indicating that the two viruses constitute a new antigenic group. Investigation of the relationship between these two agents is continuing, by means of the neutralization test.

By electron microscopy, Vero and BHK-21 cells infected with this agent showed viral particles similar to those of Bunyaviruses.

Mazoe virus: Serological relationship with Ippy virus. (J. Casals). In last year's annual report was given the result of a CF test that seemed to indicate that these 2 viruses were related; however, some doubts were at the time expressed concerning the validity of the observed cross-reaction. Subsequent CF tests using the same sample of Ippy immune serum against normal tissue and unrelated antigens have shown that the reaction against Mazoe antigen given by this particular Ippy antiserum was non-specific. Cross-neutralization tests by the intracerebral route in mice with Mazoe and Ippy viruses and their antisera have given the results illustrated in Table 28; these results show no relationship between the two viruses.

Can 50-51 (A.J.Main). This strain, originally recovered from Dermacentor variabilis in Canada, was submitted for identification by Dr. Harvey Artsob of the National Arbovirus Reference Service Toronto, Ontario. A sucrose-acetone extracted antigen was tested by complement-fixation against the following specific and polyvalent ascitic fluids with

Table 24. Brazilian isolates: Complement-fixation tests with Corriparta serogroup viruses.

Can 50-51 virus appears to be a new, ungrouped tick-borne virus.

I 77-236-17 (R.E.Shope). This virus isolated from Ornithodoros piroformis ticks, was referred for identification by Dr. K. Pavri, Pune, India. A sucrose-acetone extracted mouse brain antigen did not react by CF test with mouse ascitic fluids of group A, group B, polyvalent Australia, polyvalent Patois, group Simbu, group Guama, NIH polyvalent 2,3,4,12, polyvalent Palyam-Changuinola-Corriparta, mouse hepatitis, polyvalent Rabies-LCM-vaccinia-herpes-NDV, group Bunyamwera, and group Phlebotomus fever. The homologous reaction was 64/40. Additional tests are planned.

Identification of virus strains recovered from mosquitoes and bats in Indonesia (J. Olson). The virology and entomology Departments of the U. S. Naval Medical Research Unit No. 2, Jakarta Detachment have made collections of arthropods and small mammals from many locations in Indonesia in order to determine the geographic distribution and host ranges of arthropod-borne viruses in Indonesia. On two separate occasions arthropods were collected from areas in Sumatra where families from Java have been relocated by the Government. These sites are ideal for the transmission of arthropod-borne viruses since they bring man in close contact with forest dwelling arthropods. Each area was originally claimed from the forest and now constitutes an enclave surrounded by the forest. Many inhabitants derive all or a portion of their income from wood cutting, rubber tapping or other occupations for which they must go into the forest daily.

To date only 2 strains of virus have been recovered from the pools of mosquitoes collected in these areas. Two strains of JE have been identified from Cx. whitmorei and Cx. gelidus from South Sumatra. Two not yet identified viruses have been recovered from 2 species of bats, Eonycteris spelaea and Cynopterus brachyotis captured in West Sumatra.

In 1978 a serologic study of human and animal populations of Lombok, the Lesser Sundase, showed that neutralizing (NT) antibodies to several arthropod-borne viruses were prevalent. More than 30% of humans tested had hemagglutination-inhibiting (HI) antibody to flaviviruses. Of those

persons with HI antibody, 13% had NT antibody to Zika virus, 13% to dengue type 2 (DEN-2) and there were individuals with NT antibody to Tembusu (TMU) Kunjin (KUN) and Sepik (SEP) viruses. Domestic animals showed evidence of infection with JE, Murray Valley encephalitis (MVE), KUN, SEP, and Batai (BAT) viruses.

In March 1979, a following study was completed after the annual rains had begun. Collections were made of 144,701 mosquitoes and more than 48,000 Culicoides spp. Efforts were concentrated around animal stables and in villages where prevalences of antibodies were high. From the 1,022 mosquito pools, 13 virus strains were recovered from 8 species. No isolations were made from Culicoides spp. Table 29 shows the species from which viruses were recovered.

III. SEROLOGIC SURVEYS

Human surveys were carried out by means of the immunofluorescence test (IF) using spot-slides prepared and inactivated in other laboratories or at YARU; all sera screened at dilution 1:4.

Ghana (J. Casals). Sera were collected in June 1975, and deposited in the WHO serum center, Yale. Thus far, 146 sera have been tested with polyvalent slides containing a mixture of cells infected with Ebola, Lassa and Marburg viruses (ELM); positive sera were subsequently tested with the monovalent slides. Ten sera had antibodies against Ebola virus only; in addition one reacted with Ebola at dilution 1:16 and with Marburg at dilution 1:4. No antibodies were found against Lassa virus. This is the first report of Ebola antibodies in Ghana; furthermore, it is to be noted that these sera were collected in June 1975, one year before the first recognized outbreak of Ebola disease.

Cameroon. Anti-Ebola antibodies have been detected in 5 of 41 sera from native employees at a missionary hospital in Garoua-Bolai.

Liberia. In a continuing surveillance for Lassa virus antibodies centered in missionary hospitals in Liberia, conducted in association with Dr. J. D. Frame, Columbia University Presbyterian Medical Center, 196 human sera have been tested since January 1, 1980; 16 of them were positive.

Survey of Sinai Bedouin sera for antibody to Rift Valley fever (R.E. Shope). Thirty-three sera of Bedouins indigenous to the Sinai were submitted by Dr. T. Schwartz, Department of Epidemiology, Israeli Ministry of Health. Tests in Jerusalem had shown antibody to RVF. These results were readily confirmed by HI test using a mouse liver antigen supplied by USAMRIID, Table 30. Eight of 33 sera tested against 8 antigen units were positive. Three additional sera showed partial inhibition. One of these three was positive when screened at 1:10 dilution with Saint-Floris antigen as were 4 of RVF HI reactors. RVF and Saint-Floris reactions correlated well as would be expected since both are in the Phlebotomus fever group. The sera were also screened at 1:10 with Sindbis and West Nile antigens. Three reacted with Sindbis and 10 with West Nile. There

*Partial reaction.

was no direct correlation among RVF, Sindbis, and West Nile reactors.

These results appear to be evidence for RVF in the Sinai area although interpretation will depend on travel history of the Bedouins and on further tests to determine if these reactions are specific for RVF or are caused by exposure to other Phlebotomus fever group viruses.

Survey for antibodies to arthropod-borne viruses in Sudan (J. Meegan, D. Winograd, and T. Bucci (NAMRU-3)). It is likely the many arthropod-borne viruses which circulate in northern and southern Africa are disease problems in Sudan. Few studies have been undertaken in this geopolitically important country. During 1979, 1980, and 1981 over 1200 sera were collected from military recruits in Sudan. These represent collections from all areas of Sudan (age, birthplace, and district of residence are available for all). This survey is the first phase of a long-term study to determine the impact of arthropod-borne viruses on human beings and animals in Sudan. In addition, since Sudan may act as a tunnel for the movement of viral disease from sub-Saharan Africa to Egypt and beyond, survey for other arboviruses may give clues as to what diseases to be alert for.

To date, 708 sera have been screened by the indirect immunofluorescent (IF) test. Micro-neutralization (N) tests are in progress to validate the preliminary IF results. Table 31 presents our initial IF results. Antigens employed in these tests were viruses implicated as human pathogens in equatorial, northern, and southern Africa.

Many of the viruses to which antibodies were detected have not been thoroughly investigated. For example, the high prevalence of antibodies to Tataguine and Zinga/Bangui was unexpected, and if confirmed by N tests, would indicate these viruses are widespread in equatorial Africa. Preliminary N tests have validated that the antibodies to SAF, GOR, and Gabek Forest (GF) are specific, and thus represent human infections with these agents. IF cross-reactions and nonspecific positive fluorescence most likely make the prevalence rates in Table 31 higher than the true rate determined by N tests.

In conjunction with an ongoing survey for antibodies to Lassa, Marburg, and Ebola viruses in equatorial Africa (see other sections this report), sera from southern Sudan were screened for these antibodies. Sixty-nine sera have been tested to date; 14 were positive with the trivalent antigen slide. Four of these positive sera were tested with monovalent slides; three were positive only for Ebola, and one gave questionable results. Further testing is in progress to characterize the positive results and to evaluate sera from other geographic areas within Sudan.

IV. DIAGNOSIS OF DISEASE

Korean hemorrhagic fever (J. Casals). The application of IF to the diagnosis of KHF was made possible by the propagation of the disease's

*Results of CF tests.

etiological agent in cell cultures by H.W. Lee (1978). Spot-slides containing suspensions of a human lung carcinoma cell line - A 549-infected with KHF virus were supplied by Dr. G. French, USAMRIID; control slides with uninfected cells were also supplied. Three sets of sera were tested with these slides in an attempt to determine their suitability as diagnostic antigens:

a. Fifteen convalescent sera from previous admissions to the Hospital of the Hubei Provincial Medical College, Wuchang, China, between 1975 and 1979, with the clinical diagnosis of epidemic hemorrhagic fever (Korean hemorrhagic fever, KHF); these sera were supplied by Dr. C.M. Hsiang, of that medical school.

b. Ten paired sera from patients admitted to 3 hospitals in South Korea in 1974, clinically diagnosed as KHF; sera supplied by Dr. K.H. Kim, National Institute of Health, Seoul, Korea.

c. Single sera from 10 U.S. Army personnel, with the clinical diagnosis of KHF, in 1967-68; sera supplied by Dr. N. Wiebenga, Chief, Epidemiology Branch, Department of Health, Hawaii.

The sera were tested by IF test only at dilution 1:4, with the exception of two that were titrated out.

Results: All the sera from group a gave positive reactions with readings rating 3 or 4, except one that was considered as questionable; the reactions with the control, uninfected slides were uniformly negative.

The results with sera in groups b and c are presented in Table 32. Positive reactions were given by all the patients except #KHF-5; this may have been a false clinical diagnosis. Acute sera taken as early as the 6th day from onset were strongly positive; titrating out of two sera, J.H.L. and J.D.Y., resulted in high titers, 1:2048 and 1:512, respectively.

The results given by these 3 groups of patients simply confirm the observations by others and show that the IF test is, at this time, a reliable procedure as an aid to the diagnosis of KHF.

CCHF. A number of laboratory workers at this Unit have been involved in investigations with CCHF virus. In keeping with recent restrictions imposed on the use of this agent, all activities requiring the use of active, virulent virus have been discontinued. None of the individuals connected with work with this virus over a period of years had, at any time, an illness that could even remotely be considered CCHF. In order to determine whether subclinical or aberrant infections could be documented, sera from 7 persons who, at some time or other, participated in the work were tested by IF test against CCHF antigen on "spot-slides"; the sera were tested at dilution 1:4. The number of sera from each individual were: PB, 2; JC, 3; CM, 3; RS, 7; AS, 1; GT, 2; and HW, 5. All sera gave negative reactions; it appears, therefore, that CCHF virus can be handled in the laboratory with safety.

Identification of agents recovered from fever patients in Klaten, Central Java (J. Olson). There is serologic evidence that Zika causes fever among inpatients in Klaten. (Olson, et al., Trans. Roy. Soc. Trop. Med. Hyg., in press).

A following study in the same hospital was designed to identify the relative importance of bacteria, rickettsia and viruses as etiologic agents among inpatients. The study began in December 1978, and continued through January 1980. A total of 12 agents was recovered in Vero or BHK-21 cells from acute phase sera collected from febrile patients. Table 33 summarizes the signs, symptoms and test results of the patients from whom an isolate was recovered.

All isolates were passaged in mice or cell cultures to increase their titer and then lyophilized and sent to YARU for identification. All but one isolate (JKT Ar.Log#2555) has been recovered at YARU and titrated to contain at least $10^{4.0}$ TCID₅₀/0.025 ml. To date, unidentified agents have been set upon spot-slides for grouping by immunofluorescence test.

Fever Studies in Indonesia (J. Olson). An integral part of the arbovirus studies in Indonesia has been the performance of short term and longitudinal studies of patient populations who seek treatment. A variety of populations has been studied longitudinally and includes pediatric inpatients with encephalitis from Java, pediatric inpatients from Sulawesi with febrile illnesses, febrile inpatients of all ages from Bali, urban and rural outpatients with fever from Bali and urban inpatients of all ages with febrile illnesses. Short term fever studies of outpatients who seek medical care in government clinics were also completed in Lombok and Sumatra. In each case our protocols stressed both serologic examination and isolation of arthropod-borne viruses. All isolation attempts were completed in Indonesia and discussions of our attempts to characterize those viruses not identified as dengue are discussed in another section of this report.

Serologic examination of patients stressed the collection of acute and convalescent sera and careful completion of patient records and check list of signs and symptoms. Table 34 shows the distribution of patients, using the various studies and the serologic tests already completed for each group. Our plan is to test paired sera for neutralizing antibodies and determine the relative importance of arthropod-borne viruses as causes of illness in the samples.

We have already compiled a list of viruses known to be present in Southeast Asia and the Western Pacific, Table 35. Working stocks of these viruses are being grown to yield TCID₅₀ of $10^{-4.0}$ log₁₀/0.025 ml. for use in a microneutralization test (Ksiazek and Liu, in press). Table 36 shows the status of our efforts. Each reference strain to be used in our micro-NT test will be tested with patient sera and reference hyperimmune mouse ascitic fluids (HMAF).

Dengue virus is highly endemic throughout most of Indonesia and will

likely be the most frequently encountered etiologic agent. HI tests for flaviviral infections have already been completed and on those paired sera for which a diagnostic rise or presumptive standing antibody titer was measured, we will test in micro NT with the 4 serotypes of dengue. Those sera with flavivirus antibody, but which do not show a diagnostic increase in dengue NT antibody will be tested with other flaviviruses listed in Table 35.

Patients have also been tested for evidence of alphavirus infection by HI using CHIK, RR, and GET hemagglutination antigens (HA). Those paired sera will be tested for neutralizing antibodies using alphaviruses listed in Table 35. No tests for arthropod-borne viruses other than alphaviruses and flaviviruses have been completed.

The measurement of serum antibody in paired sera to other groups of viruses will be accomplished by indirect immunofluorescence. Patient sera showing a diagnostic rise in antibody titer from acute to convalescent phase will be tested in a micro NT test using representative viruses and antisera of the group selected from Table 36.

V. BIOCHEMICAL STUDIES

The unexpected discovery that Colorado tick fever (CTF) virus RNA has 12 segments was made early in 1980. The Orbivirus genus was first recognized as a distinct taxonomic group of arboviruses based upon the morphologic, serologic, and physicochemical data of viruses in the Yale Arbovirus Research Unit-WHO virus collection. Twelve distinct serogroups are recognized on the basis of CF cross-reactivity with one ungrouped set of viruses, and these are listed in Table 37. The Table lists 86 serotypes distinct by N test.

Double-stranded (ds) RNA segment analyses of CTF (D.L. Knudson). Results of ds RNA segment analyses by polyacrylamide gel electrophoresis indicated that representatives of serogroups of the orbiviruses had 10-segmented genomes (see 1978 and 1979 Annual Reports). Thus finding 12 segments in the CTF genome came as a surprise. The observation stimulated a more comprehensive study of the 4 other genera of Reoviridae as well as an in-depth study of different CTF isolates including clones of the Florio strain.

Representatives of the genera Rotavirus, cytoplasmic polyhedrosis virus group, and plant reovirus group were supplied as purified virus preparations; and the virus strains respectively included a human rotavirus isolated from a fecal sample, Bombyx mori cytoplasmic polyhedrosis virus, and wound tumor virus. Reovirus type 3 Dearing strain (Reovirus) was grown in L929 cells and purified following standard protocols. Changuinola, chosen to represent 10-segmented orbivirus RNA, and Colorado tick fever were grown in BHK-21 clone 13 cells and purified following the reovirus protocols. The dsRNA was purified from the virus samples following a SDS, chloroform-isoamyl alcohol extraction procedure. The dsRNA segments were end-labeled and separated by electrophoresis through a 10% acrylamide gel. Examination of an autoradiograph of the gel revealed characteristic separations of the dsRNA segments for each virus

(Figure 1). The dsRNA profiles seen with reovirus, CPV, and WTV were analogous to those reported elsewhere. The WTV isolate exhibited a thirteenth, nonmolar, low molecular weight segment which suggests that the virus was not a wild type isolate. Variants of WTV have been observed, and this isolate may be a variant.

The dsRNA profile for Changuinola virus has ten well separated bands. In contrast, CTF virus has twelve equimolar segments of dsRNA (Figure 1). The molecular weights of the dsRNA segments were calculated using the reported values of reovirus 3D, and the data are presented in Table 38. CTF virus exhibits an apparent total molecular weight of 18×10^6 daltons which is significantly larger than those of the other genera.

Three additional isolates of CTF were similarly analyzed, and they also exhibited twelve bands. The isolate used in this study was CTF-Florio strain. The dsRNA profile of 24 clones of this isolate which were randomly picked from plaques also yielded twelve segments, and one clone was plaque-purified three times in BHK-21 cells. A tissue culture virus stock was prepared of the multiply cloned virus, and a suckling mouse brain virus stock was also prepared. Identical dsRNA profiles were observed using both virus stocks as inoculum. Complement-fixation tests were also conducted using this cloned virus and NIH reference reagents. The results of these tests confirm that CTF-Florio strain virus belongs to CTF serogroup, Table 39.

This cloned stock of CTF virus is not a mixture of viruses with distinctive genotypes as assessed by its dsRNA profile, and its genome is composed of twelve segments of dsRNA which are present in equimolar concentrations. The genomes of three other isolates of CTF virus also exhibit twelve equimolar dsRNA segments. Thus, representatives of eleven of the twelve Orbivirus serogroups have ten segments of dsRNA, while the CTF serogroup is the exception with twelve segments. Since CTF virus is a novel member of the genus Orbivirus, additional characterization of the viral genome is needed. Then, a re-evaluation of its taxonomic status may be appropriate.

DsRNA analyses of Changuinola (CGL) serogroup viruses (O.F.P. de Oliva and D.L. Knudson). The Changuinola (CGL) serogroup viruses represent orbiviruses isolated in Central and South America and associated with phlebotomines in nature. CGL was first isolated from Lutzomyia spp. of sandflies and from human blood during a survey in the Almirante region of Bocas del Toro, Panama for arboviruses which lasted from 1959 to 1962. The human case was an individual who was employed as a mosquito catcher in the survey, and the case presented a mild febrile illness. CGL was serologically typed as a new agent, and it was partially characterized for its pathogenicity for mice and cell cultures. CGL was later demonstrated to be resistant to lipid solvents and to cross-react by complement-fixation with orbiviruses isolated from Oryzomys spp. and phlebotomines from Brazil. CGL was repeatedly isolated from the phlebotomines with habitats of swampforest and upland tropical rainforest ecologies during the survey. CGL isolates were made from phlebotomines in a subsequent survey for arboviruses in the Aguacate and Limbo regions of Panama over a

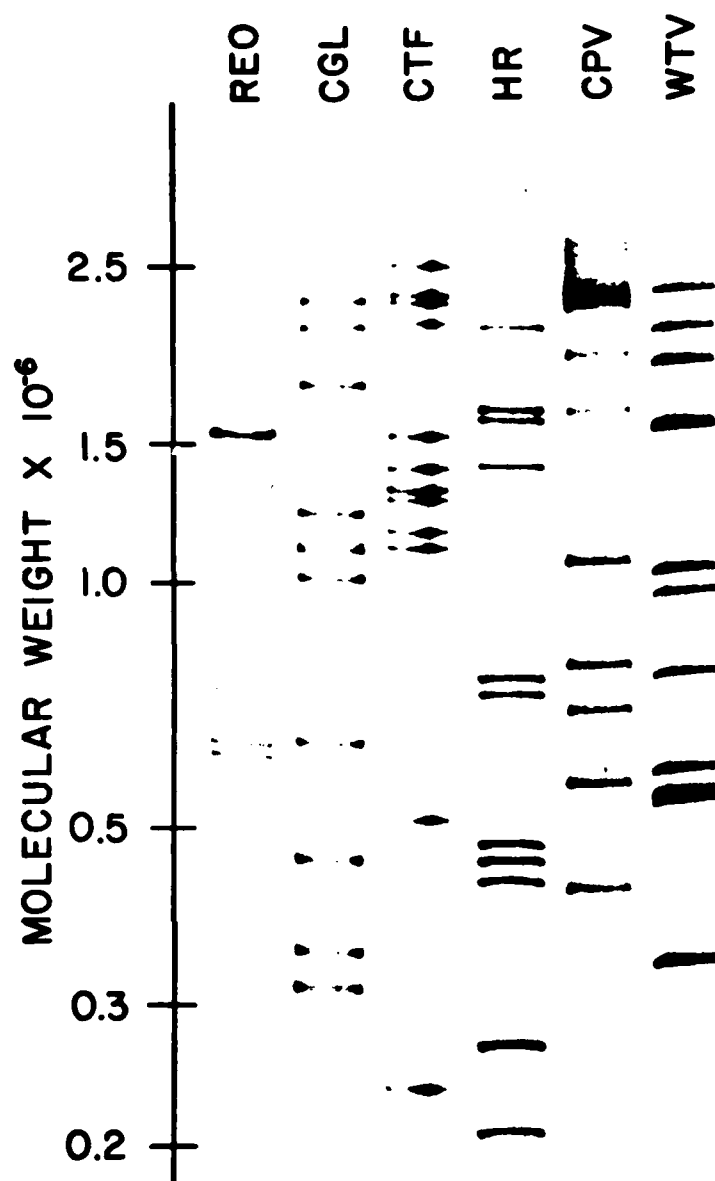

Figure 1. Autoradiogram of the genomes of representatives from the genera of Reoviridae depicting the segments for each virus and a relative molecular weight scale. The genera represented include Reovirus (Reovirus type 3 Dearing strain - REO), Orbivirus (Changuinola strain BT 436-CGL and Colorado tick fever Florio strain - CTF), Rotavirus (human rotavirus - HR), cytoplasmic polyhedrosis group (Bombyx mori cytoplasmic polyhedrosis -CPV), and plant reovirus group (wound tumor virus - WTV). Purified dsRNA was end-labeled at the 3'-end of the two strands of each segment by the addition of (5'-³²P)pCp (2000 to 3000 Ci/mmole, Amersham) using T4 RNA ligase. The samples were prepared for electrophoresis and run for 20 h at 20 mamps through 10% acrylamide. The gel was fixed, dried, and exposed to Kodak NS-5T X-ray film. The molecular weight scale was calculated using the reported values of reovirus.

total	14.75	11.39	18.06	10.35	14.24	14.57

*The molecular weights of the segments were calculated by regression analysis using the reported values of reovirus 3D. The virus abbreviations are explained in the legend of figure 1.

Table 39. Complement Fixation Tests of Plaque-purified Colorado Tick Fever Virus

Antigens	Mouse Ascitic Fluid		
	CTF	NIH-CTF	Normal
CTF (Condon strain)	128/>512	128/>512	<4/<4
CTF (Florio plaque-purified strain)	64/128	128/256	<4/<4

Complement-fixation tests were done using sucrose-acetone extracted suckling mouse brain antigens. CTF (Condon strain), CTF immune mouse ascitic fluid, and normal mouse ascitic fluid were from the Yale Arbovirus Research Unit, WHO Reference Center for Arboviruses. The NIH-CTF mouse ascitic fluid was supplied by National Institutes of Health Reference Reagents (Cat. No. V506-701-562). The data are expressed as reciprocal titers of antiserum/antigen.

period of 1969 to 1971, and again, the virus was repeatedly isolated. CGL virus has been isolated in Panama from phlebotomines, mosquitoes, and Bradypus sloths over the past eighteen years (P.H.Peralta, 1979, personal communication). These isolates are listed in Table 40. Complement-fixation tests were used to characterize some of these isolates as CGL (Table 41). CGL (BT-436), BT-104, and BT-2164 were all collected from the Almirante site, and yet, they represent distinct serotypes. Thus, the actual number of distinct serotypes remains to be demonstrated. However, there are at least eight.

This study was undertaken to examine the extent of genetic variation of the members of the CGL serogroup as assessed by PAGE analyses of the 10 segments of dsRNA. Furthermore, two new Corriparta group isolates from Brazil sent to YARU by Dr. F. Pinheiro (Belem, Brazil) in 1978 were also examined. Table 42 lists the viruses which were analyzed, and it also provides information on the history of the isolates.

The CGL isolates chosen represent viruses which were isolated at independent sites. Multiple isolations were made at the two sites, but there was a period of eight to ten years between isolations. The isolates from the Almirante site are also representative of those which have been analyzed by neutralization tests (Tables 43 and 44). CGL isolates BT-436 and BT-766 as well as BT-2164 and BT-2365 were indistinguishable by neutralization tests. The isolates from Aguacate react in CF tests with CGL, but neutralization tests have not been performed. The remaining CGL serogroup viruses are distinct in neutralization tests, and hence, they represent serotypes of the CGL serogroup. Three members of the Palyam (PAL) serogroup were also included in these analyses (Table 42).

PAGE analyses of the dsRNA of these CGL viruses yielded dsRNA profiles which correlated with the neutralization data (Figure 2). For example, the profiles for BT-436 and BT-766 were indistinguishable. Likewise, BT-2164 and BT-2365 yielded similar profiles. Although BT-104 was similar to BT-436 and BT-766, minor differences in segment mobilities were seen. Thus, the Almirante site yielded three distinct genotypes. In contrast, the Aguacate site isolates resulted in four distinct genotypes, and these genotypes were distinct from the three found with the Almirante isolates. The remaining four CGL isolates from Colombia and Brazil exhibited four new genotypes. Thus, eleven distinct profiles or genotypes were observed.

PAGE analyses of the two new Brazilian Corriparta group isolates revealed that each had a distinct profile. Likewise, the three PAL serotypes exhibited distinctive genotypes (Figure 3). A comparison of the PAL genotypes with the Brazilian genotypes suggested that the profiles between those two groups were not even generally similar.

Cloning of Tribec (TRI) virus (R. Lavendar and D.L. Knudson). Since the dsRNA profile of TRI exhibited twelve segments, the TRI virus stock was either a mixture of viruses or the genome had twelve dsRNA segments which were nonmolar in concentration. Thus, TRI should be a mixture of four distinct genotypes as assessed by dsRNA profile analyses. The TRI virus stock was cloned by a plaque-picking procedure using BHK-21 cells. The

Reciprocal of serum dilution giving 50% or greater plaque inhibition in Vero cultures (S.T. Baker, M.D. and M.P.H. Thesis, Yale University School of Medicine, 1967).

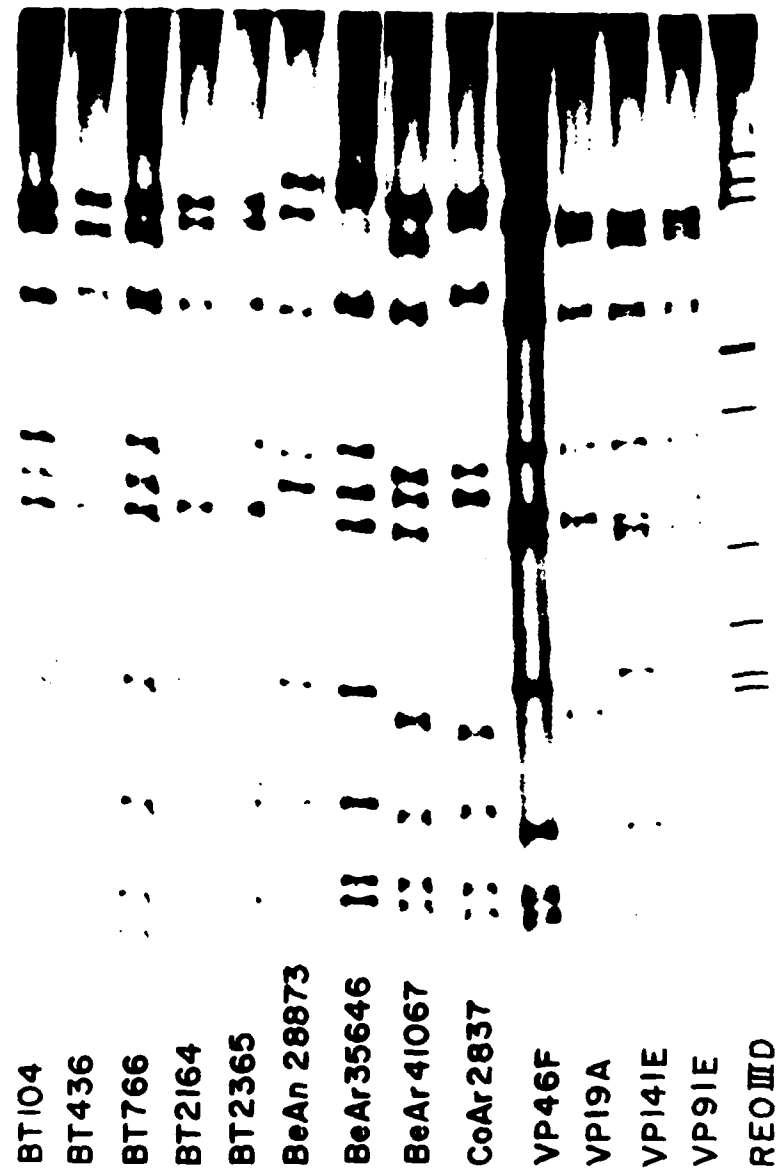

Figure 2. PAGE analysis of the dsRNA segments of each of the virus isolates tested. The segments are in order of decreasing molecular weights. The abbreviations for the gel tracks are found in table 42.

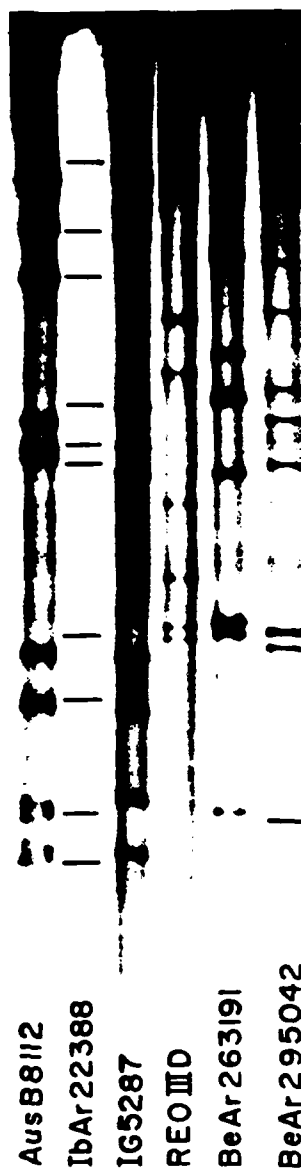

Figure 3. PAGE analysis of the dsRNA segments of each of the virus isolates tested. The segments are in order of decreasing molecular weights. The abbreviations for the gel tracks are found in table 42.

dsRNA profiles were examined from over a hundred clones in attempt to isolate the four genotypes and to determine their frequency in the original virus stock. Figure 4 represents an autoradiogram of the results for twenty clones. The four predicted genotypes were isolated, but their frequency of appearance differed for the genotypes. Three of the four genotypes were observed with equal frequencies, and one was less frequent. Thus, the TRI virus stock was a mixture of at least four genotypes each with a distinct dsRNA profile.

DsRNA analyses of other orbiviruses (D.L. Knudson). DsRNA profiles have been examined for most of the orbiviruses and many of their respective strains as listed in Table 37. The twenty serotypes of BLU virus have been recently analyzed in collaboration with the U.S.D.A. Plum Island Animal Disease Laboratory (PIADL) at Plum Island, NY. Again, distinct dsRNA patterns were observed (data not shown).

The Kemerovo-Cape Wrath complex strains which include; Bauline, Cape Wrath, Fin isolates, Great Island, Mykines, Okhotskiy, Tindhølmur, and Yaquina Head have been analyzed for their dsRNA patterns. Each serotype was distinct, and strains of a given serotype exhibited generally similar profiles with minor variations in segment mobilities. For example, the seven virus strains isolated from Great Island, a restricted ecosystem, show differences in their profiles such that four distinct genotypes were observed (data not shown).

Several of the ungrouped viruses have been analyzed, and their dsRNA patterns demonstrated that they were orbiviruses because they had ten segments of dsRNA. For example, Orungo virus from Africa exhibited ten dsRNA segments (data not shown). Orungo virus is known to be associated with febrile illness in man, and serosurveys of the Nigerian population have demonstrated CF antibody in more than 60% of those tested.

The overwhelming feature that these studies reveal is that there is extensive genetic variation in orbiviruses as assessed by their dsRNA patterns of the viral genomes. These data suggest that the majority of the isolates exhibit distinct RNA profiles of ten segments which is consistent with their classification as orbiviruses. There are instances where segments appear to co-run, and as a result, some isolates seem to have less than 10 segments. When the autoradiograms were analyzed by scanning densitometry, the segments which co-ran were noted. The RNA profiles of strains isolated from a specific geographic region were often indistinguishable. In a few instances, variation in a single segment between two strains was also seen. In general, viruses which originated from specific areas were similar, but extensive variability in the dsRNA profiles was observed for isolates from different regions. All the Orbivirus serogroups, except CTF, have genomes which are composed of ten segments.

VI. IMMUNOLOGY AND PATHOGENESIS STUDIES

Effect of immunosuppression on the pathogenicity of the 2-8 attenuated strain of Japanese encephalitis virus (B.Q.Chen and

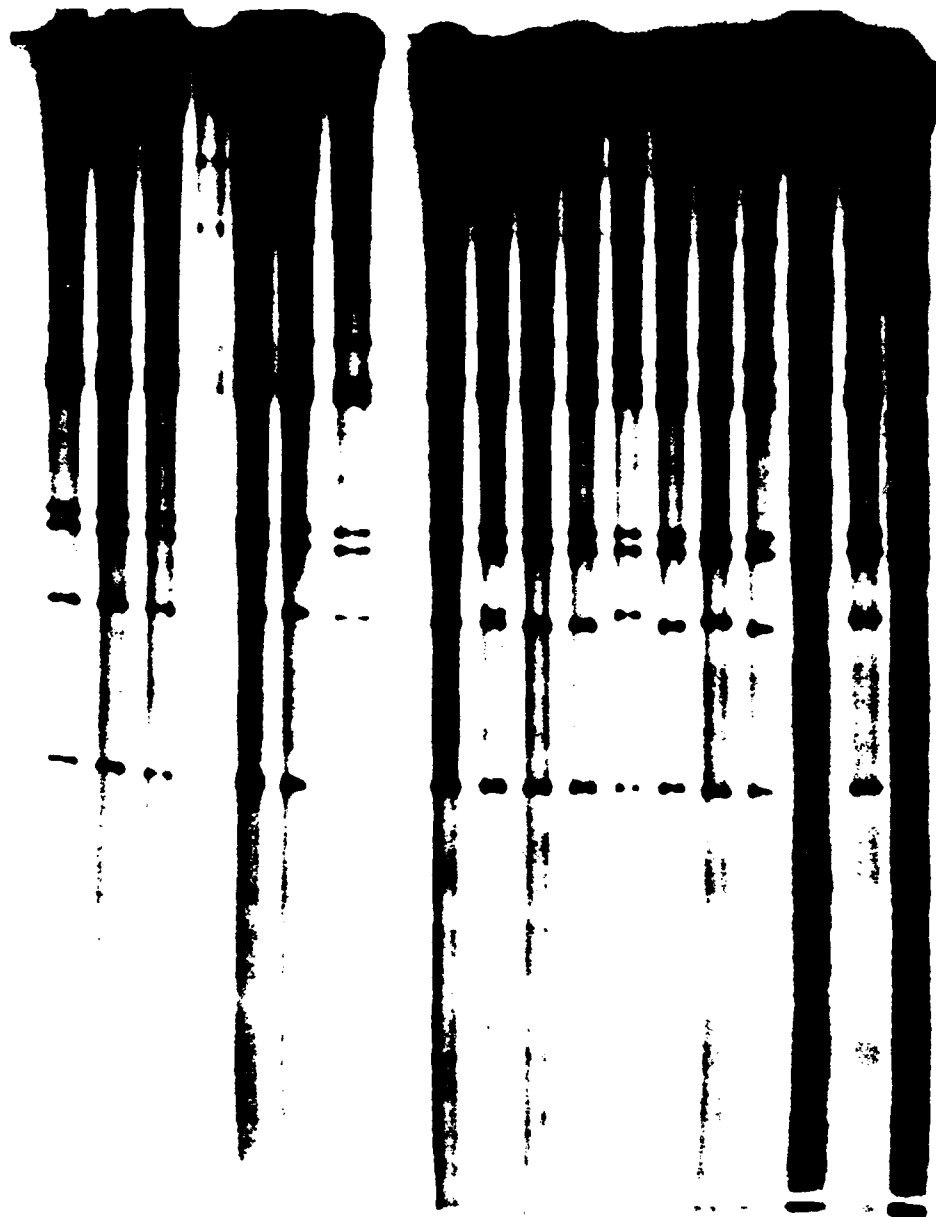

Figure 4. DsRNA profiles of Tribec clones. Four distinct genotypes were observed when Tribec clones were analyzed by PAGE. The genomic variants found show different mobilities for segments 3 and 9 (numbered from the top of the figure). An example of a mixture of genotypes as a result of inadequate cloning is shown by the gel track in the middle where two segments are seen at position 9.

G.H.Tignor). In an attempt to understand how the 2-8 strain of Japanese encephalitis (JE) virus is attenuated for mice, the 2-8 strain and the virulent parent SA14 strain were studied in outbred Swiss mice, and in CBA/J, and C3H/RV and C3H/HE inbred mice before and after cyclophosphamide immunosuppression. Mice were immunosuppressed by ip administration of 150 mg/kg cyclophosphamide on days 1, 3, and 5 after virus inoculation.

Two mice were sacrificed at 1 hr, 3 hr, 5 hr, 8 hr, 24 hr, 3 days, 5 days, and 8 days after inoculation of virus. The following were collected: blood, brain, spleen, and bone marrow. In some experiments kidney and liver were also sampled. The viruses were assayed in BHK-21 cells. Tissues were also examined by immunofluorescence.

JE 2-8 attenuated virus. The titer of 2-8 JE virus inoculum was $9.3 \log_{10}$ TCID₅₀/ml. C3H/HE mice inoculated ic or ip did not die or become ill. Mice which survived ic inoculation had HI antibody 14 days later; these mice survived challenge on the 14th day with fully virulent SA 14 virus ($8.5 \log_{10}$ TCID₅₀/ml). After ip inoculation, virus isolated from blood was of higher titer ($6.5 \log_{10}$ TCID₅₀/ml) than virus isolated from other organs until 8 hrs after injection. Virus was not isolated from the brain or bone marrow after 8 hrs, but was isolated from the spleen and blood at 3 days, but not at 5 days or 8 days.

C3H/RV (flavivirus resistant) mice inoculated ic or ip with 2-8 virus did not die and did not become ill. HI antibody was not detected 14 days later in mice inoculated ip, but these mice survived ic challenge with fully virulent SA14 virus ($8.5 \log_{10}$ TCID₅₀/ml). After ip inoculation, virus isolated from the blood was of higher titer ($6.5 \log_{10}$ TCID₅₀/ml) than virus isolated from other organs until 8 hrs after injection. The viremia ended at 8 hr. Virus was not isolated from the brain at or after 3 hr in contrast to the results in C3H/HE mice. Virus was isolated from bone marrow and spleen at 24 hr, but not at 3 days, in contrast to the results in C3H/HE mice.

Two of 10 cyclophosphamide-treated C3H/RV mice infected ic with 2-8 virus died whereas 0/10 untreated mice died. The control group given drug alone survived.

The mortality in CBA/J mice inoculated ic was 2/10; mice inoculated ip survived. The results of cyclophosphamide treatment were quite different from the results in C3H/RV mice in that immunosuppression caused death of 10/10 mice inoculated ic and 10/10 mice inoculated ip. There were no deaths among control mice given cyclophosphamide alone. Mice injected ip with 2-8 virus ($8.5 \log_{10}$ TCID₅₀/ml) and treated with cyclophosphamide were reconstituted with bone marrow, spleen cells, thymus cells, or blood taken from donor mice which had been immunized 1 month before. Recipients of bone marrow cells survived and 8/10 recipients of spleen cells survived. Four of 10 mice given thymus cells survived while all mice died given 1.0 ml of serum which had an HI titer of 1:64.

Random bred Swiss mice infected with 2-8 virus by either the ic or ip route of inoculation did not die. After ip inoculation, virus was isolated

from the blood up to 5 hr after injection. Virus was absent from the brain after 3 hr, but was isolated from the spleen, kidney, bone marrow and thymus up to day 3. Virus persisted in the bone marrow through day 8 when sampling ended. The effect of immunosuppression of random bred mice after ip injection of virus was the same as CBA/J mice in that 10/10 infected and cyclophosphamide-treated mice died. There was no mortality observed among control mice given drug alone, or among infected and untreated mice. Immunofluorescence antigen in the brains of immunosuppressed mice was widely distributed. In contrast, only isolated foci of infected cells were found in the brains of infected and untreated mice.

JEV SA-14 Virus. The dose of SA 14 virus was $9.0 \log_{10} \text{TCID}_{50}/\text{ml}$. Six of 6 C3H/HE (flavivirus susceptible) mice inoculated ic died, while 10/10 mice inoculated ip died. The virus titer in the blood of mice inoculated ip was at higher ($6.5 \log_{10} \text{TCID}_{50}$) than in other organs until 8 hrs. At 24 hrs and later, virus was isolated from the spleen and brain, but not from the bone marrow or blood.

The mortality among C3H/RV (flavivirus resistant) mice inoculated ic was 7/16; 0/10 mice inoculated ip died. Those mice which survived ip inoculation of virus also resisted challenge ic 14 days later with homologous SA 14 virus ($8.5 \log_{10} \text{TCID}_{50}/\text{ml}$). Viremia of mice inoculated ip was of a higher titer ($6.5 \log_{10} \text{TCID}_{50}$) than virus in other organs until 8 hrs. Virus was not isolated from the bone marrow at 24 hrs and 3 days; virus was isolated from the spleen at 24 hrs only.

The mortality among C3H/RV (resistant) mice inoculated ic and treated with cyclophosphamide was 10/10. Two of 10 infected and untreated mice died; controls given drug alone survived. After ip inoculation of virus, 0/10 infected and untreated mice died while 6/10 infected and treated mice died.

All CBA/J and random bred Swiss mice inoculated ic or ip with SA 14 virus died. In random bred Swiss mice there was a biphasic viremia in that virus was isolated from the blood at one hr, was not isolated at 3 hr, but was isolated from the blood at 5 hr until death. In general, virus isolated from the blood was at lower titer than virus isolated from the brain, spleen and bone marrow.

Discussion. Did the JEV 2-8 vaccine have an intrinsically lower affinity for neuronal cells than did the parent virus? The answer to the question depended to a large extent upon the mouse strain used in the comparative study. JEV 2-8 vaccine had a lower intrinsic affinity for neuronal cells in C3H mice. The conclusion is based on the following observations. First, C3H/HE (flavivirus susceptible) and C3H/RV (flavivirus resistant) mice were equally resistant to ic and ip infection with JBEV 2-8 vaccine. In contrast, JEV SA-14 virus killed C3H/HE mice by ip and ic inoculation. Secondly, immunosuppression did not significantly modify the resistance of C3H/RV mice infected ic with 2-8 virus whereas it increased mortality in C3H/RV mice infected ic with SA-14 virus.

Although JBEV 2-8 vaccine did not kill immunocompetent CBA/J or

random bred Swiss mice by either the ic or ip route of inoculation, the resistance was clearly immunologic since immunosuppressed CBA/J mice inoculated ic or ip and immunosuppressed Swiss mice inoculated ip died with an encephalitic illness. Immune bone marrow cells and, to a lesser extent, spleen cells restored resistance to immunosuppressed mice infected ip thereby confirming that cells of the reticuloendothelial system are important in mediating protection. Interestingly, antibody from the same donor mice did not confer protection upon virus-infected recipients.

Pathogenesis of attenuated 2-8 strain of JE virus in Culex tritaeniorhynchus (B.Q. Chen and B.J. Beaty) The attenuated 2-8 strain of JE virus and the parent SA 14 strain which had been passaged 14 times ic in baby mice, were tested for their ability to infect and be transmitted by C. tritaeniorhynchus. The mosquitoes were obtained from R. Baker of the University of Maryland, maintained in colony at YARU, and used at 5-10 days after emergence. Both viruses were grown and assayed in BHK-21 cells.

Intrathoracic inoculation. Maximum titers of both 2-8 and SA 14 viruses were achieved in from 4 to 6 days after intrathoracic inoculation. The SA 14 virus grew to 10^8 TCID₅₀/mosquito in two experiments. The 2-8 attenuated strain replicated equally well in one experiment and about 2 log TCID₅₀ less in a second experiment. In this latter experiment mosquitoes transmitted the SA 14 strain to mice in 16/16 attempts, but failed to transmit the 2-8 strain as measured by death of baby mice (Table 45). Tests are pending of the sera of surviving mice to see if antibody was produced.

Mosquitoes fed on SA 14 and 2-8 viruses were tested on days 12, 14 and 15 after feeding, for virus content of the whole triturated mosquito. Small amounts of 2-8 virus were detected; between 3.5 and 8.5 log TCID₅₀/mosquito were found in SA 14-infected insects (Table 46). In transmission experiments using orally-infected mosquitoes, 15/20 (75%) of SA 14-infected mosquitoes transmitted; 0/21 of the 2-8 infected mosquitoes transmitted as judged by death of exposed baby mice (Table 47).

The results are interpreted to mean that there is a defect in the 2-8 virus at the level of the gut barrier. There also may be a defect at the salivary gland level, but additional experiments are needed to confirm this.

Pathogenesis of two strains of CTF for mice (C. Reed, D.L. Knudson, and G.H. Tignor). Two strains of CTF virus, a Florio mouse adapted isolate (CTF-FMA) and a wild isolate (CTF-18), were inoculated into weanling mice intracerebrally (ic). There were no obvious changes in the CTF-18 inoculated mice, but the condition of the CTF-FMA mice deteriorated and resulted in death by day 7 post inoculation (p.i.). The amount of virus present in the brains of CTF-FMA mice was 10^4 PFU/ml or greater on day 1 p.i. The titer of virus continued to rise to a peak on day 4 and 5. Some mice inoculated with CTF-18 did not have demonstrable virus in the brain at almost any time in the experiment. The virus titers were not consistent between mice on any day nor between days, and were generally lower than those for CTF-FMA inoculated mice.

The principal site of antigen location and histopathologic lesions in the brain were different for the two strains. The major sites were in the telencephalon and diencephalon for CTF-FMA and in the cerebral cortex and pons for CTF-18. The distribution of antigen is consistent with a hypothesis that viral spread within the brain occurred in part via nerve pathways, and that the pathways were different for the two strains.

Studies of Phlebotomus fever group viruses and their reassortants for increased pathogenicity (R.E. Shope). Cloned wild-type viruses and reassortants in the Phlebotomus fever group are being supplied by the University of Alabama to test for enhanced pathogenicity in small laboratory animals. To date no increased pathogenicity, as manifested by change in ability to kill mice by peripheral inoculation or decreased average survival time, has been noted.

VII. DEVELOPMENT OF NEW TECHNIQUES

The enzyme-linked solid phase immunoassay for antibody (J. Meegan)

The enzyme-linked immunosorbent assay (ELISA) has been used for detection of antibody and antigen with a number of viruses representing several serological groups (see previous Annual Reports). The ELISA was extended to the detection of antibodies to Rift Valley fever (RVF) viruses in human sera (previously collected for diagnostic or survey purposes).

The RVF ELISA was developed using inactivated antigens. Virus bands recovered after ultracentrifugation (potassium tartrate-glycerol gradients) of either formalin inactivated tissue culture vaccine or infected mouse liver yielded excellent ELISA antigens. In convalescent human sera, antibody titers (read with a spectrophotometer) were comparable to neutralization titers and ranged from 1/10,000 to 1/50,000. Preliminary experiments using a double antibody method (antigen + unknown human serum + goat antihuman + enzyme conjugated anti-goat) improved specificity and sensitivity. Additionally, employing a sandwich method (mouse anti-RVF + antigen + unknown human sera + enzyme conjugated goat antihuman) appears to improve the ELISA to levels comparable to the double antibody method. Other experiments in progress involve the enzyme-linked fluorescent assay (ELFA) which appears to extend the sensitivity of the ELISA test and makes visual reading comparable to spectrophotometric analysis. Currently we are employing these tests to determine the time of onset and magnitude of antibodies in serial sera collected from patients with documented RVF. This collection of sera has been analysed by neutralization, hemagglutination-inhibition, complement-fixation and indirect-fluorescent antibody tests, and tested for IgG and IgM antibody response. To date, ELISA appears to parallel the neutralizing antibody response; further comparisons, and IgG and IgM antibody detection are in progress.

Parameters affecting the ELISA test also have been studied. Increasing the purity of viral antigens improves the sensitivity and specificity of the test, but the process of attaching the antigen to the solid phase (polystyrene plate) remains undefined and variable. We have developed an ELISA utilizing antigen covalently bound to a solid phase

(either agarose or polyacrylamide microspheres). Our preliminary results show these antigen-spheres can be used as antigen in the HI, ELISA, or IFA tests (and presumably will function in the CF and radioimmunoassay tests). Current studies are designed to perfect this multitest antigen and determine its ability to be lyophilized, reused, and/or employed in a polyantigen ELISA test.

ELISA to detect La Crosse antigen in mosquito pools (S. Hildreth, C. Frazier, and B.J. Beaty). The ELISA system was investigated as a possible tool to detect arbovirus antigens within mosquito pools of various sizes. The particular ELISA system used was the indirect sandwich method; comprised of a capture viral specific antibody attached to a plastic surface, followed by the test sample then by a detector viral specific antibody and then the anti-species enzyme conjugate.

Aedes triseriatus were infected intrathoracically with 20 pfu of La Crosse (LAC) virus, harvested at 15 days post-inoculation and stored at -70°C. Each mosquito was thawed and headsquashed then tested for LAC antigen by fluorescent antibody (FA) method, both direct and indirect. Mosquitoes proven FA (+) were used individually or combined with normal mosquitoes to produce various pool categories (see Table 48). The diluent for the mosquito pools was 0.02M PBS with 10% newborn calf serum and 1% penicillin-streptomycin mixture. Mosquito samples were ground with a mortar and pestle with 1.0 ml of diluent, samples were centrifuged at 800 x g for 20 min and the supernatant collected and stored at -70°C. Immediately before testing, tween -20 was added to mosquito pools to a final concentration of 0.05%.

Mouse anti-LAC antibodies were purified by Sephadex G-200 column chromatography, diluted 1:50 in 0.6 M carbonate buffer and 0.2 ml was coated to the microtiter wells (Microelisa substrate plates, Dynatech Labs., Inc.) by overnight incubation at 4°C. Plates were washed 4 times with 0.02 M PBS-tween 20 (0.05%). Mosquito pool preparations were added to the wells (0.2 ml) and incubated for 2 hours at room temperature. Plates were again washed 4 times with PBS-tween and the detector antibody (rabbit anti-LAC (NH₄)₂SO₄ precipitated Ig fraction, 1:400) was added. Following an additional 2 hour incubation (room temperature) the plates were again washed and the conjugate was added (goat anti-rabbit IgG-alkaline phosphatase, 1:750). Plates were incubated 2 more hours at room temperature. After washing, the substrate (p-nitrophenyl phosphate), 1 mg/ml in diethanolamine buffer, was added. After approximately 30 min the reaction was stopped with 3 N NaOH. Plates were read using a Titertek Multiskan (Flow Laboratories) microtiter plate reader. Replicate samples were produced for most mosquito pools. The mean of the mosquito control, normal mosquitoes in a pool of approximately the same size, served as a reference for evaluating other samples. As such, a test sample was considered positive for LAC antigen if the absorbance value was greater than 3 standard deviations from the mean of the mosquito control, matched on pool size and dilution of sample.

The possibility that mosquito tissues or viral aggregates could reduce the sensitivity of the ELISA test was examined. Selected pools,

upon thawing, were subjected to high speed centrifugation (Eppendorf, 15,600xg) for 1 min., sonification (Sonifer Cell Disruptor, 50 watts) in a -10°C ice bath for 30 sec., or both. Specificity was examined by testing pools of A. triseriatus infected with Jamestown Canyon virus, proven FA positive by the indirect method. Positive and negative controls were tissue culture fluids of LAC virus and Modoc virus, respectively.

LAC antigen was detected in as small a pool as 1 mosquito in 1.0 ml of diluent or 1 infected mosquito added to 50 non-infected mosquitoes in 1.0 ml of diluent (Table 48). The additional procedures of centrifugation and/or sonification did not appear to improve sensitivity (Table 49). Specificity of the LAC-antigen detection system appears reasonable, although this remains to be investigated further. ELISA seemed to be a sensitive and practical method for detection of arboviral antigen in mosquito preparations.

ELISA to detect Guaroa antigen in mosquito pools (K. Obom and R. Shope). Antigen detection studies using ELISA have continued on a bunyavirus (Guaroa) model system. The most sensitive procedure proved to be a four-layer sandwich method as opposed to a double-antibody method. Employing this procedure, as little as 6.6×10^4 plaque forming units (pfu) of virus were detected. The procedure detected Guaroa virus in a pool of mosquitoes containing 2 infected and 50 uninfected insects.

Monoclonal antibodies to Rift Valley fever viruses (J. Meegan). Monoclonal antibodies will be utilized not only for exploring the antigenic sites on proteins (or subunits) from Phlebotomus fever group viruses but also as a source of large quantities of purified antibodies for use with ELISA and other rapid diagnostic tests. Monoclonal antibodies are produced from hybrid cells formed by fusion of a myeloma cell line with spleen cells from an immunized mouse. Briefly, the method involves immunization of C57 BL/6 mice with 3-5 weekly doses of viral antigen mixed with equal volumes of adjuvant. Three days after the final booster spleens are removed from immunized mice and fused (using polyethylene glycol 1500) with BALB/C NSI/1 myeloma cells at a 4:1 ratio. In media containing hypoxanthine, aminopterin, and thymidine the parental myeloma cells are not viable. Parental non-fused spleen cells will not grow in cell culture. Thus, only hybridomas will grow and supernatants from these can be tested with IFA and ELISA tests for antibody production. Hybridomas producing specific antibodies can then be maintained in cell culture or inoculated i.p. in isogenic mice with the resulting ascitic fluids containing monoclonal antibody.

We have employed a number of different inactivated RVF virus antigens to immunize mice for hybridoma studies. Virus bands from ultracentrifuged (potassium tartrate-glycerol gradients) vaccine or mouse liver preparations as well as the unpurified starting materials were used in the ongoing experiments summarized in Table 50. The ELISA test was employed for the initial screening of hybridomas and periodically during growth and passage. Table 50 includes results from our earliest trials which did not yield as many hybridomas as later fusions; and the percentage of positive wells is thus somewhat low. Further testing is ongoing to determine the

specificity of the positive hybridomas and to clone all lines producing monoclonal antibodies.

Rhipicephalus appendiculatus tick cell line (LST-RA-243) for growth of Connecticut virus: need to passage infected mouse brain through cell culture to obtain susceptibility (B.Q.Chen and S.M.Buckley). Connecticut virus of the Sawgrass group was successfully grown in LST-RA-243 cells, but only from cell culture derived virus, not from infected mouse brain. Adaptation of LST-RA-243 cells to trypsinization and mass culture was described in the 1979 Annual Report (p.69). Infected mouse brain, passage 5, was used to inoculate BHK-21, Vero, and LST-RA-243 cells. CPE was noted in BHK-21 and Vero cells. In the LST-RA-243 cells there was neither CPE nor growth as determined on day 7 by subculture into BHK-21 cells. Three additional attempts to infect the tick cells with mouse brain were unsuccessful, however a single passage of Connecticut virus in BHK-21 or C6/36 Aedes albopictus cells resulted in virus stock capable of infecting the tick cells. The results are shown in Table 51.

On the possibility that either defective-interfering particles in mouse brain or simply a low-titered inoculum accounted for the inability to infect tick cells, a comparative titration of the mouse brain stock was done in C6/36 and LST-RA-243 cells. The results (Table 52) were identical whether a 1:10 or 1:100,000 dilution was used. Addition of 10% normal mouse brain to the BHK-21 inoculum did not inhibit infectivity for LST-RA-243 cells (Table 53). Growth of Connecticut virus from BHK-21 cells initially was slower in the tick cell line than in mosquito cells, however, by 72 hr the titer was 8.0 log TCID₅₀ in both cells (Table 54). A persistent infection was established in the LST-RA-243 cells with titers ranging between 6.0 and 8.5 log TCID₅₀/ml for at least 21 days.

The explanation for the inability to infect tick cells with mouse brain-infected Connecticut virus is not clear. Perhaps the mouse selects against a virus population infective for tick cells. This phenomenon is important to remember when cell line susceptibility range is under consideration.

Replication of Tyuleniy virus in both tick and mosquito cell cultures (B.Q. Chen and S.M. Buckley). Tyuleniy virus has been isolated in nature from Ixodes putus ticks in the USSR and has also been shown by Soviet workers to be transmitted experimentally by mosquitoes. Four mosquito cell lines and the Rhipicephalus appendiculatus tick cell line were inoculated with 5.5 dex Tyuleniy virus of mouse brain origin. The supernatant fluids were assayed in BHK-21 cells on days 3, 7, 14, and 25 and cells were examined for immunofluorescence on day 25. Virus titered 2.0 and 3.5 TCID₅₀/ml on days 7 and 14 respectively in the tick cells. The virus also grew well in Aedes pseudoscutellaris cells, reaching a titer of 8.5 TCID₅₀/ml by day 25. Virus was not detected in Toxorhynchites amboinensis Ta 14a cells or Aedes aegypti C 17 cells. Virus was detected in undiluted fluid of T. amboinensis Ta 12A cells on day 14 only. Immunofluorescence was found in the tick cells and in A. pseudoscutellaris cells but not in the other mosquito cell lines. This is the first time in this laboratory that a tick-borne flavivirus has been demonstrated to replicate in a mosquito cell line.

Application of the plaque reduction neutralization test (PRNT) to detect antibody induced by 17-D yellow fever vaccine during the 1978-79 Trinidad epidemic (M.J.Lewis, G.Roze, and W.G.Downs). During the yellow fever epidemic starting in November 1978, mass 17-D vaccination was carried out in Trinidad. Sera from vaccinees were sent to YARU for serological confirmation of efficacy of the program. PRNT with 17-D virus in Vero cells was done on 222 sera of vaccinees. One hundred nine were from residents of Port-of-Spain and 113 were from the rural area of Sangre Grande. Nine more were from persons vaccinated in 1976 and one in 1973. Several lots of vaccine from different countries-of-origin were represented in the sample.

Of 232 sera, all but 1 neutralized 17-D virus (Table 55) using a 50% reduction criterion. In test number 1 of Table 55, the criterion for neutralization was comparison with the positive control (Table 56) since the virus dose was apparently greater than planned.

The single non-reactor was from Sangre Grande and was said to have received vaccine manufactured in Brazil. Overall, 99.6% of vaccines had antibody, indicating a successful vaccination campaign from the sero conversion point-of-view.

Application of immunofluorescence and ELISA tests to detection of antibodies following immunization with 17D, yellow fever. (J.D. Converse, W.G. Downs, and J. Casals). The spot slides for IF tests were prepared with Asibi strain of yellow fever, in Vero cells. Antigen for ELISA tests was prepared from A. albopictus C6/36 cells infected with Asibi strain; the virus was precipitated with 10% polyethylene glycol 6000 in NaCl 2.3%. After overnight incubation at 4C, the suspension was centrifuged at 10,000 rpm for 1 hour. The pellet, resuspended in TRIS buffer at pH 7.3, was layered on a discontinuous sucrose gradient and centrifuged at 95000 g for 2 hours. The diffuse band was collected and titrated against a known system to determine the dilution at which it was to be used to cover the polystyrene plates. The ELISA test was carried out in the routine manner and the results read by means of an ELISA-READER (Titertek). End-points were calculated by interpolation, i.e., by comparison of the linear regression analysis slope of the test serum with the regression slope of the control serum, using dilutions 1:10 to 1:2560. The titer of a serum is expressed as the highest dilution which gave an O.D. (optical density) value of 0.1 or greater above the normal control.

Pre- and post-vaccination sera from 13 individuals were compared by plaque reduction test -- at 90% and 50% reduction --, hemagglutination inhibition, ELISA and IF; the results are given in Table 57. The conclusion from this study appears to be that following vaccination with 17D vaccine, neither ELISA nor IF tests detected antibodies, with few exceptions, in persons who were positive both by plaque reduction and HI tests. Furthermore, two of the 13 individuals who were strongly positive by ELISA following vaccination, were also positive with unchanged titers before vaccination.

Crimean-Congo hemorrhagic fever in Iraq (J. Casals). Between September 16 and 25, 1980, J. Casals visited Baghdad, Iraq as a WHO consultant on Crimean-Congo hemorrhagic fever (CCHF). He visited with Dr. Tantawi, University of Baghdad; Dr. Jurji, in charge of the Hemorrhagic Fevers Unit; Drs. Dabbagh, Muhedeen, Kirma, Al-Khoury, Al-Ani, and Hassan of Hummayad Fever Hospital. The gathered information is the subject of a report to WHO, the salient parts of which are given here.

The onset of the first recognized case of CCHF in Iraq was on September 3, 1979; the case occurred in Ramadi, about 100 Km west of Baghdad, where she died on September 9, 1979. Two hospital-acquired cases developed shortly after admission of the index case, a resident physician and an auxiliary nurse, both of whom died on September 19th. From that time until September 20, 1980, a total of 55 cases have been registered by the Office of the Director of Epidemiology and Quarantine (DEQ), Directorate General of Preventive Medicine, Ministry of Health.

Distribution of cases in time and space. Cases occurred sporadically throughout nearly a 12-month period, with increased accumulations in September-November, 1979, and April-June, 1980. Twenty-two cases occurred in the city of Baghdad and 33 in The Provinces. At least 2 of the Baghdad patients lived very near the hub of the city, Thahrir square; the others were located within a radius of from 7 to 10 Km of the city center.

The cases were singly and widely scattered in the capital and outside it, with no connection between any of them, with two exceptions, the index case and the two hospital-associated, secondary cases; and two sisters living in the same household who, judging from their admission dates were probably infected from the same source rather than one from the other. This distribution pattern bespeaks a widely distributed endemic situation in Iraq extending, at least, over the southern half of the area between the rivers.

Distribution of cases by sex and age. Twenty-three patients were males and 32 females; given the numbers involved the difference is not significant. The disease affected persons of all ages but was more frequently seen in youth and middle age: the number of cases in children (1-14 years) was 13; in adults, from 15 to 49 years, 35 cases; and in persons 50 years and older, 7 cases.

Clinical considerations. The clinical picture described to Dr. Casals by the clinicians at Fever Hospital was similar to that reported in other areas where the disease has occurred, USSR and Pakistan, but in its most severe form with prominent gastro-intestinal hemorrhages, extensive echymoses which in photographs seen during the consultation nearly covered the entire upper extremities and face and pronounced toxemia and dehydration; the severity of the disease is borne out by the fact that 35 of the 55 patients died and of these 35, 19 expired within 24 hours from hospital admission, probably between 6 and 8 days from onset. Death was generally attributed to shock and hepato-renal failure; complications such as pneumonia and septicemia were common.

PR=plaque reduction; HI=hemagglutination-inhibition; IF=immunofluorescence; YF=yellow fever;
JE=Japanese encephalitis.

First dilution of serum: PR, 1:8; HI, 1:10; ELISA, 1:20; IF, 1:4.

Mode of infection. According to information from several sources--DEQ, Virology laboratory, physicians at Fever Hospital--few of the patients who lived long enough after admission to be questioned associated their disease with tick-bites or any bites: they did not observe ticks biting them shortly before falling ill. On the other hand, nearly all, or their families, mentioned close association with livestock in the household, mainly sheep and goats, fewer with cattle; no special mention was made of butchering livestock shortly before the onset of illness. Some of the field epidemiologists stated that it is conceivable that tick bites among people who keep livestock are so common that they are easily overlooked or, if mentioned in connection with the disease, they are unreliable.

A few domiciliary visits during the consultation clearly demonstrated not only the close association between patients and sheep or other livestock right in the city of Baghdad, but also the fact that tick bites had been noted and remembered by some of the patients.

Specific diagnosis, Virological. Attempts to isolate virus were made in 8 or 10 of the 55 patients; 4 patients yielded virus strains. Whether a fifth patient was positive could not be definitely established due to contradictory records. In all 4 instances, the strains were specifically identified as CCHF virus by means of CF and/or IF tests with a reference mouse hyperimmune reagent.

Serological diagnosis. Results of CF tests for serum antibodies were available for 17 of the 55 patients. Fifteen of the 20 survivors had antibodies with titers from 1:8 to 1:2048 and 5 were not tested; a fatal case tested on the day of admission was negative and a second one who died after 4 days in the hospital was positive with a titer of 1:32.

No results were made available to indicate whether the 15 positive survivors had actually showed serological conversion, i.e., a four-fold or greater increase in antibody titer between early and late sera. The results supplied were the titers observed between 3 and 4 weeks after hospital admission.

Accepting CF antibody titers of 1:128 and higher as indicative of recent infection one can accept as likely that 9 cases were serologically confirmed.

Summarizing the preceeding data it can be accepted that a specific virological and/or serological diagnosis was made in 11 instances.

Entomological aspects. Four small tick pools, species and stage undetermined, were tested at the virological laboratory by inoculation to cell cultures, in attempts to isolate virus. An additional pool was sent to Porton Down. No CCHF virus was isolated from these pools.

Serological surveys: Man. A survey carried out in 1979-1980 with sera from 1,580 persons from various parts of the country showed a high proportion with CF antibodies (Al-Tikriti et al., in preparation, 1981). Among patients' relatives and contacts, 29 percent of 257 were positive; 29

percent of 233 animal breeders in northern Iraq were positive; 7 percent of 773 abattoir workers and 10 percent of 166 hospital staffs were also positive. By contrast a random sample of 151 individuals not known to have had contact with cases were all negative.

Summary. Clinical and epidemiological observations from September 1979 to September 1980 lead to the conclusion that CCHF is endemic in Iraq from the valley of the Euphrates river eastward, particularly in the central and southern part of that area including the city of Baghdad. In addition, serological surveys with human sera show antibodies against the virus; in view of the known antigenic relationships of CCHF virus, these antibodies are most likely due to activity of the virus in the populations surveyed. The wide endemicity of the disease is borne out by the distribution of cases in time and space; there is no apparent connection between cases (excepting two nosocomial infections) and they are distributed over the entire year, with the exception of two winter months. These facts indicate multiple and unrelated foci of infection.

Major unanswered questions include: How is CCHF maintained in nature in Iraq? What tick(s) is involved in reservoir maintenance and transmission to man? Is virus transmitted from blood of livestock? Are the positive serological survey results specific?

YARU, through WHO, has supplied Iraq CCHF spot-slides for immunofluorescence tests and plans to continue to do so.

IX. COLLECTION OF LOW PASSAGE YELLOW FEVER REFERENCE STRAINS (R.B. Tesh).

One of the recommendations of the PAHO-sponsored Yellow Fever Symposium, held in Belem, Brazil in April 1980, was that an effort should be made to collect and preserve low-passage strains of yellow fever virus from various regions of Africa and the Americas for future reference. Accordingly, letters were sent to a number of virus laboratories located in areas where the virus is endemic. To date, 15 strains have been received. These are listed in Table 58. A stock of each virus strain has been prepared in cultures of Aedes albopictus cells (C6/36 clone) and has been lyophilized for storage. These specimens are available for distribution to interested investigators.

X. DISTRIBUTION OF REAGENTS, WHO COLLABORATING CENTRE FOR REFERENCE AND RESEARCH (R.E. Shope, J. Casals, A. Main, S. Buckley, G.H. Tignor, J. Meegan). The equivalent of 668 ampoules of arbovirus reagents were distributed from the WHO Centre to laboratories in 23 countries during 1980. This total consisted of 326 ampoules of virus stock, 136 ampoules of virus antigen, and 191 ampoules of mouse immune ascitic fluid or sera. Of the viruses and antibody distributed, there were represented 196 different arboviruses.

During 1980, the equivalent of 612 ampoules of arbovirus reagents was referred to this Centre from laboratories in 20 different countries. The

referrals consisted of 278 viruses (Table 59), 276 ampoules of antigens, and 58 ampoules of immune reagents. In addition, 1,186 sera were received for arbovirus antibody survey testing.

Eight different cell lines were distributed in 1980. The lines and recipients are listed in Table 60.
